(Dated: February 1, 2008)

We propose two protocols to encode a logical qubit into physical qubits relying on common types of qubit-qubit interactions in as simple forms as possible. We comment on its experimental implementation in several quantum computing architectures, e.g. with trapped atomic ion qubits, atomic qubits inside a high Q optical cavity, solid state Josephson junction qubits, and Bose-Einstein condensed atoms.

The extreme power of quantum information processing originates from the coherence properties of quantum states, manifested in terms of entanglement between different local (physical) qubits [1]. In recent years, a variety of physical qubits have been realized, and controlled qubit-qubit interactions demonstrated, pointing to a promising future for large scale quantum computing technology. However, the much studied environment induced decoherence and dissipation will inevitably destroy quantum coherence, leading to unavoidable errors of physical qubit based quantum information.

The most remarkable difference between quantum and classical errors is due to the fact that quantum errors are continuous, thus can not be simply corrected with known error correcting schemes from classical information theory. In 1995, Shor made the important discovery that 9-qubit based logic qubit can correct arbitrary quantum errors, despite their continuous nature [2]. Following this landmark achievement, quantum error codes [3, 4] and fault tolerant quantum computing [5, 6, 7] have been extensively studied, significantly boosting the confidence in practical quantum computation.

The continued development of quantum information science highlights the importance of mapping physical qubits into logic qubits. In an error correcting procedure as we now understand, encoding a logic qubit into physical qubits is the important first step that introduces extra freedom to store less information in order to recover from errors. In addition, the logic qubit basis state can be chosen to be a decoherence free subspace, offering the potential advantage of completely eliminating environment induced decoherence [8, 9, 10]. Of all architectures considered for experimental quantum computation, the encoding of logic qubits into physical qubits has only been accomplished, and in fact, used extensively in ensemble based NMR systems. A simpler version, encoding a qubit into a two dimensional decoherence free subspace was recently demonstrated with two trapped ions [10].

In this study, we investigate the proper interactions needed for realizing efficient encoding of logic qubits. We suggest two protocols that accomplish the intended encoding of an unknown qubit relying on simple interactions as commonly used in the generation of maximally entangled states of various two state systems, e.g., Bose-Einstein condensed atoms [11], trapped atomic ions [12],

cavity QED systems [13], and solid state Josephson junctions [14]. In what follows, we will first detail our protocol for a model of many qubits. This is followed by more specific discussions of several physical systems where our model can be applied; we then conclude with a brief summary of our study.

We start with a statement of the problem being considered here in this article, i.e. encoding of an unknown logic qubit into physical qubits. The unknown qubit takes the general form $\alpha|0\rangle + \beta|1\rangle$ with coefficients α and β and orthogonal computation basis states $|0\rangle$ and $|1\rangle$. The logic qubit typically involves several qubits and is capable of correcting certain types of error. As a simple example, we first consider an encoded logic qubit in terms of the repeated state (of N additional qubits) that reads $\alpha|\underbrace{0, \dots, 0}_{N+1}\rangle + \beta|\underbrace{1, \dots, 1}_{N+1}\rangle$. This encoding clearly can correct bit flip errors as long as the number of flipped qubits is less than half of the total $(N+1)$, despite its extreme sensitivity to phase errors. In the end, we will also give explicit steps for constructing the 9-qubit Shor code [2] that corrects all known types of 1-qubit errors.

Our initial logic qubit thus uses a total of $N+1$ physical qubits with the first physical qubit being the given (unknown) qubit. Without loss of generality, the initial state of our system is thus

$$|\psi(0)\rangle = (\alpha|0\rangle + \beta|1\rangle) \otimes |\underbrace{0, \dots, 0}_N\rangle, \quad (1)$$

with N assumed even. Relying on pair wise interactions, a straightforward encoding would involve the use of N CNOT gates with the first physical qubit as control and each of reminder N qubit as target. This strategy of using repeated CNOT gates is clearly not the most economical protocol for our intended encoding. As our investigation will show, there exist more efficient protocols that use common types of qubit-qubit interactions in a collective way to accomplish the encoding in as simple forms as possible.

One of the interaction terms, the collective Hamiltonian we intend to use for encoding, is $H = uJ_x^2$ with $J_x = \hbar \sum_{j=2}^{N+1} \sigma_x^{(j)}/2$ (or equivalently J_y^2 or J_z^2 as in Ref. [11]). $\sigma_x^{(j)}$ is the Pauli matrix of the j th qubit. Such

a Hamiltonian is symmetric and takes a simple collective form. Its importance has been recognized by several groups in the study of generating maximally entangled or spin squeezed states [11, 12]. We assume the interaction strength u is controllable, i.e. can be turned on and off to affect the dynamics of the N added qubits. In the second quantization language, with $a(a^\dagger)$ and $b(b^\dagger)$ as the annihilation (creation) operators for the qubit state $|0\rangle$ and $|1\rangle$, we find the expression $J_x = (b^\dagger a + a^\dagger b)/2$, completely symmetric with each of the N -qubits.

Previous studies [11, 12] have shown at time $\tau_1 = \pi/2u$, the Hamiltonian uJ_x^2 will evolve the initial $|\phi_0(0)\rangle = |\underbrace{0, \dots, 0}_N\rangle$ into a maximally entangled state, or a GHZ state of the N qubits

$$|\phi_0(\tau_1)\rangle = \frac{1}{\sqrt{2}}[e^{-i\frac{\pi}{4}}|\underbrace{0, \dots, 0}_N\rangle + e^{i(\frac{\pi}{4} + \frac{N}{2}\pi)}|\underbrace{1, \dots, 1}_N\rangle]. \quad (2)$$

By symmetry, the initial state $|\phi_1(0)\rangle = |\underbrace{1, \dots, 1}_N\rangle$ also evolves into a maximally entangled state

$$|\phi_1(\tau_1)\rangle = \frac{1}{\sqrt{2}}[e^{i(\frac{\pi}{4} + \frac{N}{2}\pi)}|\underbrace{0, \dots, 0}_N\rangle + e^{-i\frac{\pi}{4}}|\underbrace{1, \dots, 1}_N\rangle]. \quad (3)$$

At time $\tau_2 = 2\pi/u$, i.e. a period of evolution from the initially separable states $|\phi_{0/1}(0)\rangle$ to a maximally entangled states $|\phi_{0/1}(\tau)\rangle$ and then back to the initial separable states, we end up with $|\phi_0(\tau_2)\rangle = |\underbrace{0, \dots, 0}_N\rangle$ and

$$|\phi_1(\tau_2)\rangle = |\underbrace{1, \dots, 1}_N\rangle.$$

Based on the above dynamics of uJ_x^2 periodically creating maximally entangled states from separable states, we devise the following protocol for efficiently encoding an unknown logical qubit into physical qubits. We start with the initial state as given in Eq. (1).

First, we turn on the uJ_x^2 interaction of the N qubits [from the 2nd to the $(N+1)$ -th]. After a duration of τ_1 , the complete quantum state becomes

$$|\psi(\tau_1)\rangle = (\alpha|0\rangle + \beta|1\rangle) \otimes |\phi_0(\tau_1)\rangle. \quad (4)$$

We now turn off the uJ_x^2 interaction and turn on another interaction $\sigma_z^{(1)}\sigma_z^{(2)}$ between the first physical qubit and another one selected arbitrarily from the other N qubits. This second interaction is necessarily similar to that required in the detection of the maximally entangled states as it provides individual addressability for at least one of the additional N qubits, as discussed by Itano *et al.* [15]. After an additional duration τ , this second interaction leads to $|00\rangle \rightarrow |00\rangle$, $|01\rangle \rightarrow |01\rangle$, $|10\rangle \rightarrow |10\rangle$, and $|11\rangle \rightarrow -|11\rangle$, i.e. a simple phase gate between the physical qubit and an arbitrary one of the N additional qubits. In fact, other gates, such as a CNOT can also be used here as a substitute to effect our protocol, although

additional single bit rotations may be needed in this case. The state of our system then becomes

$$|\psi(\tau_1 + \tau)\rangle = \alpha|0\rangle|\phi_0(\tau_1)\rangle - i(-1)^{N/2}\beta|1\rangle|\phi_1(\tau_1)\rangle. \quad (5)$$

We then turn off the $\sigma_z^{(1)}\sigma_z^{(2)}$ interaction and turn back on the uJ_x^2 interaction for the last N qubits again and after a time $\tau_2 - \tau_1$ we finally obtain

$$|\psi(\tau_2 + \tau)\rangle = \alpha|\underbrace{0, \dots, 0}_{N+1}\rangle - i(-1)^{N/2}\beta|\underbrace{1, \dots, 1}_{N+1}\rangle, \quad (6)$$

i.e., exactly what the encoding task calls for apart from a known relative phase factor $-i(-1)^{N/2}$ between the logic qubit basis states $|\underbrace{1, \dots, 1}_{N+1}\rangle$ and $|\underbrace{0, \dots, 0}_{N+1}\rangle$. This

phase factor can be easily eliminated using single qubit rotations without knowing the coefficients α and β .

Now we turn to the second protocol for the same encoding that uses only the uJ_x^2 type interaction and single qubit measurement. The required addressability of a particular qubit from the N appended qubits to effect the $\sigma_z^{(1)}\sigma_z^{(2)}$ interaction as in the first protocol is now eliminated. Starting from the same initial state (1), we now assume N odd for simplicity with $N+1$ being an even number. This second protocol is possible because of an important observation that the Hamiltonian $H = uJ_x^2$ also evolves the initial state $|\underbrace{1, 0, \dots, 0}_{N+1}\rangle$

to a maximally entangled state $\frac{1}{\sqrt{2}}e^{-i\pi/4}(|\underbrace{1, 0, \dots, 0}_{N+1}\rangle + i(-1)^{N/2}|\underbrace{0, 1, \dots, 1}_{N+1}\rangle)$. Therefore, the second protocol

consists of the following: First we apply the interaction uJ_x^2 to all the $N+1$ qubits of $|\psi(0)\rangle$. This leads to the time evolved state (apart from an overall phase) at time $\tau_1 = \pi/2u$

$$\begin{aligned} |\psi(\tau_1)\rangle &= \alpha(|\underbrace{0, 0, \dots, 0}_{N+1}\rangle + e^{i\phi}|\underbrace{1, 1, \dots, 1}_{N+1}\rangle) \\ &\quad + \beta(e^{i\phi}|\underbrace{1, 0, \dots, 0}_{N+1}\rangle + |\underbrace{0, 1, \dots, 1}_{N+1}\rangle) \\ &= |0\rangle(\alpha|\underbrace{0, \dots, 0}_N\rangle + e^{i\phi}\beta|\underbrace{1, \dots, 1}_N\rangle) \\ &\quad + |1\rangle(\alpha e^{i\phi}|\underbrace{1, \dots, 1}_N\rangle + \beta|\underbrace{0, \dots, 0}_N\rangle), \end{aligned} \quad (7)$$

with $\phi = (N+1)\pi/2$.

Then we measure the first physical qubit in the σ_z basis: if we get $|0\rangle$, the encoding task is accomplished preceded by a single qubit rotation to get rid of the $e^{i\phi}$; if we get $|1\rangle$, then another uJ_x^2 interaction for a period π/u can be applied to the other N physical qubits to exchange the place of $|0\rangle$ and $|1\rangle$. This exchange of basis states can also be achieved using simultaneous single bit Rabi oscillations. As before, single qubit rotations are

needed to get rid of the phase factor $e^{i\phi}$ and to take into account the fact that for N odd, a linear interaction J_x is also needed [12].

The above two theoretical protocols have three distinct features of the encoding procedure. First, all operations are independent of the details of the initial physical state, i.e., an unknown logic state can be encoded into corresponding physical qubits. Second, the complexity of the encoding operation is not enhanced with the increase of the number of physical qubits in one logic qubit. Third, the model interactions used are of relative simple forms, and have already been engineered in several real physical systems.

We note that the sensitivity to phase errors of the above logic qubit can be easily overcome with a basis rotation. By applying $(\pi/2)$ Rabi pulses to all qubits, we effectively affect the Hadamard gate to all qubits, leading to a logic qubit $\alpha|\underbrace{+, \dots, +}_{N+1}\rangle + \beta|\underbrace{-, \dots, -}_{N+1}\rangle$, that clearly

can correct phase errors as long as the number of error qubits is less than half of the total $(N+1)$. In the following, we discuss the various implementations of the above encoding protocols within several architectures of experimental quantum computation efforts.

Firstly, trapped atomic ions has emerged as one of the most attractive prospective quantum computer architectures, setting the standard for rudimentary quantum logic operations on several qubits [16, 17, 18]. The strong Coulomb interaction between qubits is internal state independent, and permits quantum information to be controllably transferred and entangled between several neighboring ions sharing the same quantum data bus of a collective vibrational mode. When irradiated by external laser fields, both types of interactions as required above for the encoding protocol have been demonstrated before, in particular, the uJ_x^2 type interaction was used to entangle 4 separate ions without individual addressing from the external laser fields [12, 19] and the $\sigma_z^{(1)}\sigma_z^{(2)}$ is equivalent to a CNOT operation between two neighboring ions, where a variety of equivalent protocols have been also engineered [17, 18]. Furthermore, within this system, we can even imagine the physical qubit to be of a different type of ion from the remainder N ion qubits, as recently shown in the experimental work on sympathetic cooling of ions [20]. Thus its state can be prepared and individually addressed, resolved, or detected using its frequency space (internal state) selectivity, eliminating the difficult task of focusing onto the tight space of each ion qubit in an array of trapped ions.

As an application of the encoding protocol suggested above, we show that the Shor nine qubit code [2] can be directly implemented. Starting with the (physical) qubit $\alpha|0\rangle + \beta|1\rangle$, we append 8 additional ion qubits from the same trapped ion array. On application of our encoding protocol, the logic qubit simply becomes

$$\alpha|0,0,0\rangle|0,0,0\rangle|0,0,0\rangle + \beta|1,1,1\rangle|1,1,1\rangle|1,1,1\rangle, \quad (8)$$

where the ions are grouped into triplets in preparation

for the Shor coding scheme. Now for each group of the three ion qubits, we turn on the uJ_x^2 interaction as induced from two Raman matched external laser fields [12]. After a duration of τ_1 , and from Eqs. (2) and (3), we accomplish the Shor coding

$$\begin{aligned} & \alpha[\frac{1}{\sqrt{2}}(|0,0,0\rangle - |1,1,1\rangle)]^{\otimes 3} \\ & + \beta[\frac{1}{\sqrt{2}}(|0,0,0\rangle + |1,1,1\rangle)]^{\otimes 3}, \end{aligned} \quad (9)$$

upto an additional phase factor between states $|0,0,0\rangle$ and $|1,1,1\rangle$. (Note however that single qubit operations are also needed in addition to uJ_x^2 as $N = 3$ being an odd number [12]).

Secondly, the recent success of quantum computation with superconducting Josephson junctions has raised the interests of the solid state device and material science community. While it remains completely unclear what types of physical systems the future's quantum logic devices will be embedded in, the hardware industrial base of the Information Technology does lend support for a solid state based architecture [21]. Since the demonstration of quantum coherent two states in terms of a charge qubit, flux qubit, and the charge-phase qubit, significant gains have been accomplished in this direction [22]. Already two independent groups have reported the observation of entanglement and correlation between two separate Josephson junction qubits [23, 24]. A number of theoretical proposals have suggested system implementations for the required interactions uJ_x^2 and $\sigma_z^{(1)}\sigma_z^{(2)}$ or its equivalent forms [14, 21].

Thirdly, cavity QED based quantum computing architecture occupies an unique place in quantum information science because it allows for coherent exchange of quantum information between material (atomic) and photonic qubits [13, 25, 26]. When carried by photons, qubits enjoy such a weak coupling to the environment that they can easily be distributed over very large distances through optical fibers or free space, offering prospects for distributed quantum computation and quantum communications. In currently pursued cavity QED systems, trapped ion arrays or neutral atoms intersect a high Q optical cavity, leading to a scalable geometry with several atomic qubits that can collectively share the same quantized cavity mode, a quantum data bus of the electromagnetic field [13, 27]. A mapping to an equivalent ion trap system can be easily established, leading to the recognition that both types of interactions needed for our encoding protocol can also be realized provided several experimental challenges, especially the precise localization of each atom's position inside the small cavity, can be met [28, 29].

Finally, the tremendous success of trapped atomic quantum gases has also impacted atomic physics based quantum computing efforts. Atomic Bose-Einstein condensates display remarkable phase coherence and in addition, have demonstrated controllability over atomic interactions and spatial arrangements [30, 31]. While it is

not entirely clear how to perform (distinguishable) qubit based quantum computation with Bose condensed (identical) atoms, it is evident that the collective interaction uJ_x^2 arises naturally in all multi-component condensates as well as spatially disconnected condensates [11]. The second type of interaction is more difficult to imagine at first sight, because being a system of identical particles (bosons), it becomes impossible to identify a 2nd qubit for an interaction $\sigma_z^{(1)}\sigma_z^{(2)}$ with the first physical qubit. Nevertheless, one might imagine loading an atomic condensate into an optical lattice, and by mechanically moving the trapped physical qubit into a particular lattice site, one could engineer $\sigma_z^{(1)}\sigma_z^{(2)}$ using the exchange interaction [32], or perhaps with atomic dipolar interaction as was suggested in Ref. [33]. The lattice based atom interaction among different sites, can also be easily arranged to be of the form uJ_x^2 without knowing which site is empty or filled [34].

Before concluding, we hope to address two important questions regarding our protocol for encoding a logic qubit. First, can our protocol be made fault tolerant? The simple answer is probably a yes, although sacrificing simplicity and efficiency of the collective interaction. Our protocol aims at an economical approach to encode an unknown logic qubit into physical qubits, not at the more complex question of fault tolerant quantum computation in the current study [35]. Yet the simple version of fault tolerance with concatenated codes [36] can be similarly implemented as we demonstrated above that our logic qubit basis states can be easily transformed to the Shor code, which is capable of correcting arbitrary single bit errors. Thus, our code can be made fault tolerant at least through concatenation if the errors are not collective. If, however, the errors are correlated in the symmetric J_x^2 interaction, then potential problems do arise that will become subjects of our future study. Second, does the requirement of error correction negate the benefit in complexity that is at the heart of our protocol?

Our encoding protocol leads to the simple logic qubit Eq. (8) capable of correcting only “discrete” bit-flip errors, not the more general “continuous” errors. We do not believe this is a draw as experimental effort in logic codes is still at its infancy, and any proof of principle protocol will benefit its development. Furthermore, as we have also shown, that with a few extra steps and at the cost of requiring single bit addressing, we arrive at the more advanced Shor code, capable of correcting all “continuous” single bit errors. Including the overhead of these extra steps, our protocol still represents a significant reduction in complexity for constructing the Shor code as compared to the more straightforward approach with individual quantum gates.

In conclusion, we have suggested two protocols for encoding a logical qubit into physical qubits. The first one uses two types of interactions: a collective symmetric interaction uJ_x^2 among the appended qubits and an individually resolved qubit interaction $\sigma_z^{(1)}\sigma_z^{(2)}$ between the physical qubit and any one of the appended qubits. The second one requires only a collective symmetric interaction uJ_x^2 and single qubit measurement. We have aimed for the most economical types of interactions, being simple and as symmetric as possible. While the particular encoding scheme does not seem to offer much advantage over the more sophisticated error correcting schemes, e.g. 5-qubit and 7-qubit codes as discussed in theory, we have shown the our code directly leads to the realization of the 9-qubit Shor code. In addition, our work suggests a new milestone to calibrate various experimental efforts in quantum computation; we note that previous milestones have been 1), the demonstration of a physical qubit, and 2) the demonstration of qubit-qubit entanglement; we hope our work will shed light on the continued progress of quantum information science [37].
